Abstract For the strong expression of genes in plant tissue, the availability of specific gene regulatory sequences is desired. We cloned promoter and terminator sequences of an apple (*Malus x domestica*) ribulose biphosphate carboxylase small subunit gene (*MdRbcS*), which is known for its high expression and used *gus* reporter gene expression to test the regulatory activity of the isolated promoter and terminator sequences in transgenic tobacco. The *MdRbcS* promoter itself seemed to be less strong than the *CaMV35S* promoter when both used in combination with the *nos* terminator. However, the combination of the promoter and terminator of *MdRbcS* was able to drive *gus* to similar expression levels as the reference construct with *CaMV35S* promoter and *nos* terminator. This observation indicates the importance of the terminator sequence for gene expression. It is concluded that the combination of the *MdRbcS* promoter and terminator is a suitable regulatory sequence set for the expression of transgenes to a high level in plants and for intragenesis in apple specifically.

Keywords Apple · Gene promoter and terminator · Genetic modification

Introduction

In the production of genetically modified (GM) crops that are to be directly consumed by humans, there is a tendency

to use preferentially genes and gene regulatory sequences that originate from plants themselves, rather than from, e.g., micro-organisms. Social studies aimed to elucidate factors determining consumer's attitude toward GM crops indicate that such crops are likely to be accepted much more readily. Lusk and Sullivan (2002) found that consumers would prefer GM vegetables with genes coming from the same species. Taking this concept as a starting point, different scenarios can be envisaged.

Important for the introduction of a new trait by genetic modification are the function of the gene that is used and the expression of that gene. Expression is regulated by genomic DNA sequences that flank the coding region at its 5'- and 3'-ends. The 5' upstream sequences or promoters determine the level of expression and the tissue specificity or timing, e.g., developmental stage or after induction by biotic or abiotic stress. For optimal desired performance, new combinations of coding regions and regulators might be made for genetic modification. Still, both types of DNA sequences can be taken from the recipient species. This type of genetic modification is referred to as intragenesis (Rommens et al. 2004). In case the gene or genes are used in their original configuration, which is with their own promoter and terminator regions, introns and in a sense orientation, this type of genetic modification has been called cisgenesis (Schouten et al. 2006; Schouten and Jacobsen 2008).

In our apple genetic modification program, a promoter was needed ensuring high level of transcription in many tissue types, comparable to the constitutive *CaMV* (cauliflower mosaic virus) 35S promoter, but obtained from apple. The promoter of the gene coding for the small subunit of the ribulose biphosphate carboxylase (RBC) has been studied extensively (Khouidi et al. 1997; Nomura et al. 2000; Gittins et al. 2000; Outchkourov et al. 2003) in both

homologous and heterologous crops and was found to be able to provide strong transcriptional activity. RBC is one of the most abundant proteins in the plant kingdom and can constitute 40–60% of total leaf protein. The enzyme is composed of eight small and eight large subunits encoded respectively by the nuclear and the chloroplast genome (Jensen and Bahr 1977). The RBC small subunit (*RbcS*) genes constitute a gene family of 2–12 members that contribute to varying extents to the total transcriptional activity (Outchkourov et al. 2003). The expression of the genes is observed in photosynthetically active tissue and is regulated by light (Dean and Leech 1982). Expression levels of heterologous genes driven by *RbcS* promoter sequences in different crops range between half that obtained by the *CaMV35S* promoter to seven to eightfold higher than *CaMV35S* (Outchkourov et al. 2003; Khoudi et al. 1997). In apple, Gittins et al. (2000) tested heterologous *RbcS* promoters of tomato and soybean and concluded that they would be suitable for expression in green photosynthetic tissues. Also, the *RbcS* promoter of chrysanthemum was tested in our laboratory in apple, and strong transcriptional activity could be demonstrated (F.A. Krens, pers. communication). However, these heterologous promoters are not suitable for intragenesis in apple.

Here, we describe the isolation and cloning of the *RbcS* 5' and 3' regulatory sequences of apple, based on homology to *RbcS* sequences of other crops, and the preparation of an expression cassette. The expression cassette was combined with the *gus* reporter gene and used in transformation of tobacco and apple. Expression levels were quantified in tobacco and were compared to the levels obtained using the constitutive *CaMV35S* promoter.

Materials and methods

Isolation of genomic DNA

Genomic DNA was isolated from young leaves of the apple cultivar Elstar according to the method described by Doyle and Doyle (1987), including 1% (w/v) polyvinylpyrrolidone-10 in the DNA extraction buffer.

Genome walking

Isolation of 5'-end (promoter) and 3'-end (terminator) flanking genomic sequences of the apple *RbcS* gene (*MdRbcS*) was performed following a genome walking protocol. In short, eight different in vitro genomic DNA libraries of the apple cultivar Elstar were constructed by digesting genomic DNA with eight different blunt-end cutting restriction enzymes followed by a ligation of an

adapter to the ends of the restriction fragments. The adapter is described by van der Linden et al. (2004). The libraries were used as templates in a genome-walking PCR in which, for the amplification of promoter fragments, two primers specific for the 5'-end of the *MdRbcS* cDNA sequence (GenBank accession number L24497), pGSP1 (5'-GTGAATGTGTGATGGTGGTTCGCTCT-3') and pGSP2 (5'-AGGTTATCTATTAGGGTGCCTTTGTTG-3'), and for the amplification of terminator fragments, two primers specific for the 3'-end of the *MdRbcS* cDNA sequence, tGSP1 (5'-AGGGTCCCGTGGTCTGTTAAGTTTG-3') and tGSP2 (5'-TCGGATTCAAGATGGTGTGGT TGAGA-3'), were used together with adapter-specific primers (van der Linden et al. 2004). Maximase™ Polymerase (Transgenomic) was used for amplification. Following a primary and nested PCR, different PCR fragments were obtained, and two putative promoter fragments of 0.9 and 1.6 kb, amplified from an *HpaI*- and *Hinc*-digested genomic DNA library, respectively, and a putative terminator fragment of 1.1 kb, amplified from a *Hinc*-digested genomic DNA library, were cloned in a PCR cloning vector pGEM-T Easy (Promega) and completely sequenced.

Construction of transformation vectors

For the construction of expression vectors, two *MdRbcS* genomic fragments of 1,232 and 1,679 bp located directly upstream of the translational start and a single *MdRbcS* genomic fragment of 582 bp located directly downstream of the translational stop of *MdRbcS* were amplified by PCR using genomic apple DNA as template (primers: 1.6-kb 5'-end fragment: pMdRbcS1.6-FW, 5'-TTAATTAAGTGTG GACCATCTCAGAGT-3' + pMdRbcS-REV, GGCGC GCCATGGCATTGCTCTCTCTCTCTGTTTTCTCTTC; 1.2 kb 5'-end fragment: pMdRbcS-1.2-FW, TTAATTA GACGGTGATAAATCATTCTTTGTCT + pMdRbcS-REV; 0.5 kb 3'-end fragment: tMdRbcS-FW, 5'-CCATGG TACCGTTGTTCTACAATTTTCATAAATAATGTTGT-3' + tMdRbcS-REV, 5'-GGCGCGCCGTTTGTTACAC TACCCTAAGGTC-3'). The promoter and terminator fragments included the *MdRbcS* 3'-UTR and 5'-UTR, respectively. For cloning of the promoter sequences, *PacI* and *AscI* + *NcoI* restriction sites were attached to the forward and reverse primers sequences, respectively (restriction site sequences underlined), and for cloning of the terminator, *NcoI* + *KpnI* and *AscI* restriction sites were attached to the forward and reverse primers, respectively. The amplified *MdRbcS* promoter and terminator sequences were cloned in pGEM-Teasy, and the sequences were verified by sequencing. For promoter study, two lengths of 1,200 and 1,600 bp of the *MdRbcS* promoter (*p1.2MdRbcS* and *p1.6MdRbcS*) were combined with the

terminator (*tMdRbcS*) sequence by introducing the terminator as *NcoI*-*AscI* fragment behind the promoter sequences. Both resulting vectors (p1.2 + *tMdRbcS* and p1.6 + *tMdRbcS*) contain the *MdRbcS* promoter and terminator sequences separated by an *NcoI* and a *KpnI* site. As reporter gene, an intron containing β -glucuronidase (*GUS*) gene (*gus*) was amplified using the vector pCambia1301 (GenBank accession number AF234297) as template. For this, a forward primer starting at the *gus* start codon (Gus-start, 5'-CCATGGTCCGTCCTGTA GAAACCCCAAC-3') and a reverse primer located at the *gus* stop codon (Gus-stop, 5'-GGTACCTCATTG TTTGCCTCCCTGCTGCGTT-3') were used. The forward and reverse primers were extended with an *NcoI* and *KpnI* site, respectively, to facilitate cloning. As a control, the promoter of the cauliflower mosaic virus 35S gene (*pCaMV35S*) and the terminator of the *Agrobacterium tumefaciens* nopaline synthase gene (*tnos*) were used, and these were also amplified from pCambia1301, together with the *gus* reporter gene. For amplification of *pCaMV35S* + *gus*, a primer designed at *pCaMV35S* (p35S-FW, 5'-TTAATTAACATGGAGTCAAAGATTCA AATAGAG-3'), which was extended with a *PacI* site, was used together with primer Gus-stop, and for amplification of *gus* + *tnos*, a primer designed at *tnos* (tnos-REV, 5'-GGCGCGCCCGATCTAGTAACATAGATGACAC-3'), which was extended with a *AscI* site, was used together with primer Gus-start. Finally, a fragment with *pCaMV35S* + *gus* + *tnos* was amplified using primers p35S-FW and tnos-REV. The amplified *gus*, *pCaMV35S-gus*, *gus-tnos*, and *pCaMV35S* + *gus* + *tnos* fragments were cloned in pGEM-Teasy, and the sequences were verified by sequencing. The *gus* fragment was introduced as *NcoI*-*KpnI* fragment into both vectors p1.2 + *tMdRbcS* and p1.6 + *tMdRbcS*, which were opened by digestion with *NcoI*-*KpnI*. The *pCaMV35S-gus* fragment was combined with the *MdRbcS* terminator by introducing it as *PacI*-*KpnI* fragment in vector p1.2 + *tMdRbcS*, which was opened by digestion with *PacI* and *KpnI*, thereby removing the *MdRbcS* promoter, and the *gus-tnos* fragment was combined with both *MdRbcS* promoters by introducing it as *NcoI*-*AscI* fragment in vector p1.2 + *tMdRbcS* or p1.6 + *tMdRbcS*, which were opened by digestion with *NcoI* and *AscI*, thereby removing the *MdRbcS* terminator. In total six different combinations of promoter and terminator sequences were constructed (*p1.2MdRbcS-gus-tMdRbcS*; *p1.2MdRbcS-gus-tnos*; *p1.6MdRbcS-gus-tMdRbcS*; *p1.6MdRbcS-gus-tnos*; *pCaMV35S-gus-tMdRbcS*, and *CaMV35S-gus-tnos* (see Fig. 1)), and these were introduced as *AscI*-*PacI* fragments in the multiple cloning site of the binary vector pBINplus (van Engelen et al. 1995). The ultimate constructs were transferred to the super-virulent *A. tumefaciens* strain Ag10 (Lazo et al. 1991).

Fig. 1 Schematic representation of the different promoter–terminator combinations used for plant transformation

Plant transformation

For expression analysis of the cloned promoter fragments, transgenic tobacco (*Nicotiana tabacum* cv. Samsung) plants containing T-DNA with the different promoter-*gus* terminator constructs were produced according to Horsch et al. (1985). For each construct, 15 independent kanamycin-resistant transgenic tobacco lines were selected, and per construct two to four transgenic lines showing intense GUS staining of leaf tissue were selected for further analysis.

Apple cv. Gala was transformed with the *p1.6MdRbcS-gus-tMdRbcS* constructs only. Transformation was performed according to Puite and Schaart (1996).

Histochemical GUS assay

Histochemical GUS staining of plant material was performed as described by Jefferson (1987) using a modified staining solution containing 1 mM 5-bromo-4-chloro-3-indolyl β -glucuronide (X-gluc) in 50 mM sodium phosphate buffer (pH 7.5), 10 mM EDTA, 0.1% (v/v) Triton X-100, 0.5 mM potassium ferricyanide, and 5% (w/v) polyvinylpyrrolidone-40.

Quantitative (RT)-PCR

For quantification of *gus*, expression levels and of *gus* gene copy number quantitative (RT)-PCR was performed. For quantification of *gus* expression levels, total RNA was isolated from in vitro leaves of *N. tabacum* transgenic plants basically as described by Asif et al. (2000). For each transgenic line, two independent RNA isolations were performed. cDNA was synthesized using the IScript first-strand cDNA synthesis system for RT-PCR (Biorad) according to the instruction manual. For quantification of *gus* gene copy number, genomic DNA was isolated using the CTAB method of Doyle and Doyle (1987). Quantitative (RT)-PCR was performed as described by Schaart et al.

(2002) using the MyiQ Single-Color Real-Time Detection System (BioRad, USA), but instead of the fluorogenic TaqMan probes, SYBR Green was used for detection of PCR products. For amplification of *gus*, the forward and reverse *gus*-primers (5'-CGGAAGCAACGCGTAAACTC-3' and 5'-TGAGCGTCGCGAACATTACAT-3') were used (product size 80 bp). As endogenous control, the elongation factor 1 α gene (*EF1 α*) from *N. tabacum* (GenBank accession number AF120093) was selected as a reference gene (forward *EF1 α* primer 5'-GATTGGTGG AATTGGTACTGTC-3', reverse *EF1 α* primer 5'-AG CTTCGTGGTGCATCTC-3', product size 130 bp). All PCR reactions were performed in duplo. For the real-time analysis, PCR products were detected directly by monitoring the increase in fluorescence from the incorporated SYBR green dye. The amplification was plotted as the normalized reporter signal, ΔR_n (the reporter dye was normalized to the internal reference dye and corrected for the baseline value), toward the number of PCR cycles. For each reaction, the threshold cycle, C_T , which is defined as the PCR cycle at which a statistically significant increase of ΔR_n is first detected, was determined. The relative quantification was done using the comparative C_T -method in which the differences in the C_T for the *gus*-amplicon and the C_T for the endogenous control *EF1 α* , called ΔC_T , were calculated to normalize for the differences in the total amount of cDNA or gDNA copies present in each reaction and for cDNA, the efficiency of the RT step. For comparison of two samples, the ΔC_T values were subtracted from each other, giving a $\Delta\Delta C_T$ value, and finally, the relative amount of *gus* mRNA or gDNA copies was calculated by $2^{-\Delta\Delta C_T}$.

Results

Isolation of *MdRbcS* promoter and terminator fragments

Using a genome walking protocol, several DNA fragments were amplified from the 5'- and 3'-flanking genomic regions of an *MdRbcS* gene. For this reverse primers located around the start-codon of the *MdRbcS* gene (together with adaptor primers) were designed for amplification of putative promoter sequences, and primers located

around the stop-codon of the *MdRbcS* gene were designed for amplification of a putative terminator sequence. Two putative promoter fragments of 0.9 and 1.6 kb were cloned and sequenced (GenBank accession numbers HM222640 and HM222639, respectively), and a single putative terminator fragment was also cloned and sequenced (GenBank accession number HM222641). The first 260 bp of both promoter sequences near the transcription start showed a high level of similarity (91% identity) but more distal from transcription (from start similarity was low (46% identity)). Blasting of the promoter sequences showed that they were sharing partial homology to promoter sequences of *RbcS* of different other plant species. Both putative *MdRbcS* promoter sequences contain a TATA-box and several other putative *cis*-acting elements like two GATA-boxes (Fig. 2), which are known for their light responsive activity (Castresana et al. 1988). Also an element showing similarity to a GT-1 binding box II, which was identified in the promoter of pea *RbcS-3A* (Green et al. 1987), is present in the *MdRbcS* promoter. This element is associated with high expression levels of *RbcS-3A* in pea. Polymorphisms that discriminate both promoter fragments were all located outside the predicted *cis*-acting elements (Fig. 2). The terminator sequence contained two polyadenylation signals, 70 and 116 bp downstream of the translational stop codon.

Construction of expression vectors

For the cloning of the promoter, two sizes of 1.2 and 1.6 kb were taken. The promoter fragments were amplified from genomic DNA using forward primers that were based on one of the cloned 5'-flanking sequences of the *MdRbcS* gene. The reverse primer was located directly upstream of the start-codon of the *MdRbcS* gene, so the amplified sequence included the 5'-UTR. Both promoter sequences differed only in a few single nucleotide polymorphisms. For cloning of the *MdRbcS* terminator, a similar approach was followed using a forward primer just downstream of the stop-codon of *MdRbcS* (so, including the 3'-UTR) and a reverse primer that was based on the cloned 3'-flanking sequence of the *MdRbcS* gene. For convenient cloning, appropriate restriction sites were included into the primers. For comparison of the regulatory function of the isolated

promoter and terminator sequences, the *CaMV35S* promoter and the *nos* terminator were used as reference. The six possible combinations of the three promoters (*p1.2MdRbcS*, *p1.6MdRbcS*, or *pCaMV35S*) with the two terminators (*tMdRbcS* or *tnos*) were made and combined with the *gus* reporter gene and cloned into the binary vector pBinplus.

Expression study in tobacco and apple

The different promoter-*gus* terminator constructs were transformed to tobacco, and for each construct, approximately 15 independent kanamycin-resistant lines were selected. In vitro leaves from all transgenic lines were checked for *gus*-expression by a histochemical GUS-assay. For each construct, the transgenic lines showed variation in staining intensity from low to high level of blue staining (results not shown), indicating that all promoter-terminator combinations were able to drive *gus* expression to high levels. No clear difference in staining intensity was found between plants transformed with the different constructs. For each construct, a number of independent transformed tobacco lines, which showed a clear uniform blue staining

of in vitro leaf tissue plant, was selected for quantitative gene expression analysis. Using quantitative RT-PCR, it was determined that on average, lines with the *gus* reporter gene under regulation of the *MdRbcS* promoter showed a lower *gus* expression level than lines transformed with *pCaMV35S-gus* (Fig. 3; Table 1). Both *MdRbcS* promoters did not differ significantly in their activity when combined with the *MdRbcS* terminator, but when combined with the *nos* terminator, *gus* expression driven by *p1.6MdRbcS* was significantly lower (unpaired Student's *t* test; $P < 0.05$) than for *p1.2MdRbcS*. For all three promoters used, the presence of the terminator sequence of *MdRbcS* resulted in significantly higher expression levels when compared to the use of the *nos* terminator (Fig. 3; Table 1). The use of the *MdRbcS* promoters combined with the *MdRbcS* terminator gave comparable *gus* expression levels as the *CaMV35S* promoter combined with *tnos* did.

To investigate the effect of transgene copy number on the transgene expression level for the different plant lines, the relative transgene copy number was estimated using Q-PCR (Table 2). The average ΔC_T value of a group of plant lines with a corresponding large ΔC_T value, and thus a

Table 1 Comparison of average *gus* expression levels in leaves of transgenic tobacco lines transformed with the different promoter-*gus* terminator constructs

Plant line	Promoter	Reporter	Terminator	Average expression	<i>tMdRbcS</i> vs <i>tnos</i>
1	<i>p1.2MdRbcS</i>	<i>gusi</i>	<i>tMdRbcS</i>	0.88 (± 0.32)	3.1

$\Delta\Delta C_T$ was calculated by using the average ΔC_T (*gus-EF1*) of the low copy number plant lines 1–13, 1–18, 2–4, 5–3, 5–14 as calibrator

**Fig. 4** Composition of four photographs showing regenerating shoots (white arrows) of apple cv. Gala that was transformed with a binary vector with *p1.6MdRbcS-gus-tMdRbcS*. Blue staining indicates presence of GUS activity

similar low copy number, was used as calibrator. Half of the transgenic tobacco plants contained a relatively low number of transgene copies, but in some plant lines, high transgene copy number was found. No clear correlation was observed between transgene copy number and transgene expression level (Table 2).

In order to test the functionality of the apple rubisco promoters in transgenic apples, the *p1.6MdRbcS-gus-tMdRbcS* construct was transformed to apple cv. Gala. Several calli that produced shoots on kanamycin containing shoot regeneration medium were stained for the presence of GUS activity. Most regenerated shoots showed a strong blue staining (Fig. 4).

Discussion

For the intragenic expression of genes in apple, the availability of suitable apple regulatory sequences is desirable. Our goal was to isolate gene regulatory sequences which drive gene expression in leaf tissue to a high level comparable to that of the *CaMV35S* promoter. The *RbcS* family is a photosynthesis-associated nuclear gene which is known to be highly expressed in green photosynthetic tissues and was therefore a suitable candidate to isolate regulatory sequences from. Gittins et al. (2000) tested *RbcS* promoters of tomato and soybean in apple and concluded that they would be suitable for expression in green photosynthetic tissues. They found that *RbcS* promoters of the different origins were able to drive *gus* expression to half that of plants containing the *CaMV35S* promoter.

Although the coding regions of different *RbcS* gene family members are highly similar, the level and pattern of expression can vary considerably (Anisimov et al. 2007; Sawchuk et al. 2008). The apple *RbcS* gene we used in this study to isolate regulatory sequences from shows homology to the *RbcS1A* gene subfamily from *Arabidopsis thaliana*, which was maximally expressed in differentiating and mature leaf mesophyll cells of *Arabidopsis* (Sawchuk et al. 2008). Following a genome walking approach, 5'- and 3'-flanking genomic DNA sequences of *MdRbcS* were amplified, cloned, and characterized. In order to study the two isolated putative *MdRbcS* promoters and the putative *MdRbcS* terminator sequence independently, the *CaMV35S* promoter and the *nos* terminator, which are generally used in genetic modification studies, were used as reference, and different combinations of promoters and terminators with the *gus* reporter gene were made and tested in tobacco. Based on Q-RT-PCR analysis of transgenic tobacco leaf material, we could conclude that the *MdRbcS* promoter was able to drive *gus* expression to a relatively high level, but the promoter was less active than the

CaMV35S promoter. Furthermore, Q-RT-PCR data revealed that the presence of the terminator of *MdRbcS* had a positive effect on *gus* gene expression. Dean et al. (1989) reported for the first time in plants that sequences 3' to the coding region (of petunia *RbcS*) had a significant effect on transcription rate. This finding was confirmed by Ingelbrecht et al. (1989) who showed that terminator sequences of different plant genes modulated the level of gene expression in plant cells in a different way. In their study, the presence of a terminator sequence from an *Arabidopsis RbcS* gene enhances transcription of the *nptII* gene threefold, when compared to the presence of the terminator of the *A. tumefaciens* octopine synthase (*ocs*) gene. They also showed by deletion analysis of the 3'-flanking region of the *ocs* gene that sequences downstream of the polyadenylation signal are required for optimal gene expression. These observations indicate the importance of the terminator sequence for (trans)gene transcription. Although the *MdRbcS* promoter combined with the *nos* terminator was inferior to the reference construct in which the *CaMV35S* promoter and the *nos* terminator were combined, the *MdRbcS* promoter combined with the *MdRbcS* terminator gave similar high *gus* expression as the reference construct. Therefore, the combination of both the *MdRbcS* promoter and terminator is a suitable regulatory sequence set for the expression of transgenes to a high level in plants and for intragenesis in apple specifically. A preliminary test of the functionality of the *p1.6MdRbcS-gus-tMdRbcS* construct in apple resulted in an intense blue staining in a histochemical GUS staining of regeneration transgenic apple shoots, suggesting the *MdRbcS* promoter and terminator combination to be strongly active in apple plant tissue. Whether the *MdRbcS* promoter and terminator combination drives gene expression also to a high level in mature leaves and if the combination is also active in other tissues, for example in the fruit skin green photosynthetic active tissue, has still to be investigated. In apple, the *MdRbcS* promoter-terminator combination would be suitable to confine the expression of, for example resistance genes, to the leaves which is an important site of infection for microbial diseases and insect pests. Currently, we are testing the suitability of the *MdRbcS* promoter and terminator for overexpression of the apple *HcrVf* scab resistance genes (Belfanti et al. 2004) in GM apples.
